Abstract

Reliability for businesses begins with management and how they communicate the need for a failure free environment to mobilize actions to preserve operable systems and processes. The need for reliability considers cost of alternatives to prevent or mitigate failures, which require knowledge about times to failure, and failure modes which are found by reliability technology. Justifications for reliability improvements require knowing: 1) when things fail, 2) how things fail, and 3) conversions of failures into time and money. Reliability engineering principles help define when and how things fail to provide facts for life cycle costs comparisons. This helps decide the lowest long-term cost of ownership driven by a single estimator called net present value for converting hardware issues and alternatives into money issues. Several short examples illustrate the methodology.

Reliability

Processes, components, equipment, systems, and people are not perfect and not free from failures. In a naïve, simplistic, and deterministic view, we can have perfection with perfect reliability. In the real world we fall short of perfection (perfection exists only in a fantasy world). Everything fails either because of events or from aging deteriorations. A natural law of entropy expresses the lowest energy state as a failure—buildings always fall down, they never fall up which means we must continually maintain processes and equipment to prevent disorder and failures. This requires spending time and resources to mitigating failure effects as nothing lasts forever.

Reliability is the probability that a component, system, or process will function without failure for a specified length of time when operated correctly under specified conditions. Reliability engineering is a strategic task concerned with predicting and avoiding failures. For quantifying reliability issues it is important to know *why*, *how*, *how often*, and *costs* of failures. Reliability issues are bound to the physics of failure mechanisms so the failure mechanisms can be mitigated. In the real world all potential failures are seldom well known or well understood which makes failure prediction a probabilistic issue for reliability analysis.

Reliability *is not* the same as availability although both are described as a value between 0 and 1. *Availability* tells the percent of time the system is alive and ready for use if called upon, and stream factors define the actual online times as a percentage of up time. *Reliability* addresses the probability for a failure free interval under specific conditions. Reliability is the sweet absence of failures. Unreliability is the sour presence of failures which cost money.

Risk assessment models connect money with failures in a simple equation: $Risk = (probability of failure during a specified time interval and under specific conditions)*($Consequence of the failure event). $Risks always exist, and they are never zero. How much $Risk is affordable becomes a business issue. If the business organization is risk averse, then perhaps $Risk values must be less than say $10,000, or if risk accepting, then less than say $100,000. Set the actual $Risk value as a business decision rather than "backing into it" by failure to make a decision. Society expects planning for success and rejection of abnormal $Risks. In the end, reliability is all about money for industrial businesses.

What does your reliability policy say?

Management presents important issues to the organization with policy statements. Policies define specific areas of concern and indicate the desired outcome. Policies increase decisiveness by removing uncertainty about action required to meet the objective. Policy statements communicate information to the staff in general terms for detailed implementation by procedures in a consistent fashion through individual acceptance and individual commitment. Good policies reduce the potential for bad events such as inefficiency, counter productivity, inappropriate risk taking, and conflicts over requirements so that nothing is implemented because of the void.

Modern organizations have safety policies, quality policies, and environmental policies. These existing policies have clear and simple statements calling for zero lost time injuries, zero shipments of defective products, and zero environmental releases—these are reliability statements in specific areas where they indicate the absence of failures. Reliability issues for processes and equipment also need a clear and concise policy statement to avoid fuzzy interpretations.

For your policy, can you consider saying: **We will build and maintain an economical and failure free process which will operate for 5 years between planned outages.** Management must set the reliability policy (the general directive for what is intended). Policy drives procedures (step-by-step instructions for implementing policies). Procedures drive the rules (statements to take or not take actions).

Reliability policies must integrate safety, quality, risk, and financial requirements for the company to achieve the business objectives. Reliability policies must be understandable to the common person and come from top levels of management for credibility, legitimacy, constancy of purpose for improvements, and setting the organization to work for a common objective.

Management has a big role in reliability issues, which guide design of equipment and continues through maintenance of equipment and systems. Management must address the issues and state the general requirements so everyone understands. The issue of reliability is to provide a failure free environment for the process while expecting loss of components and equipment. Management must think in terms of a chess game strategy—pawns will be lost (pumps, valves, instrumentation), but don't loose the king, which is the process including pressure integrity and product delivery system protecting human safety and environmental situations.

Management must also set an environment so everyone knows the cost for failures—it can't be a secret for those that need to make financial decisions and procedures must be established to communicate the costs of assumed values or calculated values for communicating to the organization the high cost of certain failures. The fact that a human life is priceless does not compute but society allows certain risks, which then allow calculated values for communication purposes, as time/costs is the language of commerce, decisions, and action. Examples could be:

Assumed values-
- Spill loss of 1 gallon of undesirable fluids = $500
- Spill loss of 100 gallons of undesirable fluids = $3,000
- Spill loss of 1,000 gallons of undesirable fluids = $250,000
- Spill loss of 10,000 gallons of undesirable fluids = $1,900,000
- Spill loss of 100,000 gallons of undesirable fluids = $20,000,000
- Violation of Clean Waters Act provides civil penalties of $25,000/day or $1,000/bbl of spilled material or $3,000/bbl for "gross negligence".

Calculated values -
- Accidental death of one person at (probability of failure=10^{-4}) = $2,500,000, multiply by 4 for disablement
- Accidental death of 10 people at (pof=10^{-6}) = $250,000,000, ditto for disablement

Assumed values only for communication purposes-
- Other items to provide guidelines for failure events or failure avoidance including lists of applicable specifications and regulations for compliance audits.

- If the events occur in a sensitive area increase the cost by a factor of 5, if the events occur in a benign environment, reduce the cost by a factor of 5.

Please note: These numbers are quantified merely to convert humanitarian and violation issues into money (the language of business) so business trade-off decisions can be made, and the values **are not intended** to be guidance values for lawyers, **nor** do they represent callous viewpoints about the value of human life.

The point for inclusion of failure details into the procedures is to convert failure issues into money as a guideline for the organization to think about tradeoffs so everyone can react in a logical fashion to make honest and unemotional decisions concerning reliability matters. The probability of failure for one person at 10^{-4} (Taylor 1994) is the same as reliability = 0.9999 and 10^{-6} is reliability = 0.999999. Reliability values for discussions about humans are more palatable and less emotional than probabilities for human failure! Also note the \$Risks for humans is at a lower allowed value than \$Risk for other typical business events.

Reliability Models

Reliability engineers discuss issues with reliability and availability models with a challenge, which is balanced against a capacity for handling the challenge of adverse conditions (Modarres 1999). Some systems and processes have a specific inherent capacity to handle challenges. In general, when the challenge is less than the capacity we have success; and when not, then we have failure. The failure mechanisms are physical processes attacking the models.

Typical reliability models are:

Stress-Strength models where stress represents aggregation of challenges and external conditions, and strength represents the variability of conditions affecting the capacity of system to repel the challengers attempting to cause failure.

Damage-Endurance models are similar to stress-strength models but the stress causes damages that are irreversible and cumulative such as corrosion, wear, embrittlement, and fatigue. Failure occurs when the cumulative damage exceeds the capacity of the component or system capacity to cope with the insults.

Challenge-Response models are conditions where components or systems fail but the failure is not identified until a challenge occurs due to a critical event, as compared to typical situations such as those that occur from the passage of time/cycles, etc.

Tolerance-Requirements models have failures only when the performance characteristics fall outside of some predetermined fixed limits and gradual degradation occurs based on use or time.

Mechanical failure mechanisms are physical processes, which lead to or result from some sort of stress (think of stress is general terms). The three broad classes are:

Stress-induced failure mechanisms are the cause or result of permanent or temporary stresses and are categorized by brittle fracture, buckling, yield, impact, ductile fracture, or elastic deformation.

Strength-reduced failure mechanisms lead directly or indirectly to failure and are categorized by wear, corrosion, cracking, diffusion, creep, radiation damage, or fretting.

Stress-increased failure mechanisms have a direct effect on increasing the applied stress and are categorized by fatigue, radiation, thermal-shock, impact, and fretting.

Electrical failure mechanisms are often more complicated than the typical mechanical system because of device and the packages in which they reside. Thus electrical/electronic failure mechanisms are often divided into three broad classes:

Electrical stress mechanisms result from voltage levels that damage devices or degrade electrical/electronic characteristics and are categorized by human error, uncontrolled currents, uncontrolled voltages, localized heating/melting, and latent damage, resulting in later failures.

Intrinsic failure mechanisms are related to the electrical/electronic element and categorized by electrically active layers in semiconductor chips, infant mortality problems built into the

devices by manufacturing/design problems, gate oxide breakdown, ionic contamination, surface charge spreading, and hot electrons.

Extrinsic failure mechanisms are external failure mechanisms stemming from device problems and problems with interconnections and undesirable environmental conditions.

Each failure mechanism can be accelerated in the field by unexpected combinations of events. The events are often triggered by a situation acting as a catalyst for failure.

The age-old technique for coping with these challenge events has been to make the components, systems, and processes very strong and keep the loads very low. For example, Roman bridges built for horses and chariots now carry heavy trucks with great success.

Another method of mitigating failures is by maintenance engineering techniques, however, maintenance cannot restore strengths in original designs which never existed. Thus direct replacement maintenance efforts cannot improve inherent reliability, but only restore to the original values—however, upgrade replacements can provide greater capacity.

Reliability Engineering vs. Maintenance Engineering

Reliability engineering is concerned with the strategic task of predicting and avoiding failures. Maintenance engineering is concerned with quickly restoring failures to an operating condition as a tactical task.

A current management fad is to take a maintenance mentality organization and change job titles to include the word reliability. This provides style but no substance, as tools and approaches for reliability and maintenance are different as night and day. Then management wonders why the new "reliability" organization continues to function as before when the maintenance approach was fast repairs, which were considered the key to success as dictated by a maintenance organization.

Both reliability engineering and maintenance engineering have roots in each others territory and thus must know about each others roles, responsibilities, and tools   Consider this analogy observed in most local fire departments: *reliability is to the fire marshal as maintenance is to fire fighters*. Reliability technology predicts failures and with the use of longer-range tools reduces the cost of failures.

Preventing failures costs money for equipment, procedures, and nurturing of the system. Repairing failures costs money. Thus both reliability and maintenance activities are ruled by money just as improvement decisions are always about money and alternatives. Improvement projects require engineering details converted into costs for yearly time buckets so as to correctly define cash outflows. Many companies use 10-year to 20-year intervals for study periods.

Engineering is responsible for defining when failures will occur so they can be priced in net present value (NPV) worksheets. This relies on predictions from reliability engineers for the mode of failure also provides information about failure severity. The cost of failures must also include gross margin losses from production outages and cutbacks (when appropriate)—this is particularly true for continuous process operations when the production is "sold out".

Reliability Engineering Tools

For reliability issues we talk about the sweet part—the absence of failures. We quantify reliability issues by measuring the failures, which is the sour part. Failure of equipment and processes always occur as a natural outgrowth from the laws of physics and changes in entropy of the system. It is easy to kill equipment. It is very difficult to make equipment survive.

Table 1 shows a short list of reliability tools used for predicting failures and finding cost effective alternatives. A successful reliability program requires detailed knowledge of the tools and how to make them function in the industrial world. Notice the tools are directed at "fact based" issues rather than "warm fuzzies".

Table 1 starts with arithmetic for mean times to failure and grows to more complicated analysis.

Table 1
Short List Of Reliability Engineering Principles Tools

• **Mean time between failures indices**	• **Bathtub curves for modes of failure**
• **TPM and reliability principles**	• **Availability, maintainability, capability**
• **Preparing reliability data for analysis**	• **Critical items significantly affecting safety/costs**
• **Decision trees merging reliability and costs**	• **Quality function deployment**
• **Weibull, normal, & log-normal probability plots**	• **Mechanical components testing for interactions**
• **Corrective action for Weibull failure**	• **Electronic device screening and de-rating**
• **Models & Monte Carlo simulations**	• **Quality function deployment**
• **Pareto distributions for vital problems**	• **Reliability testing strategies**
• **Fault tree analysis**	• **Accelerated testing**
• **Design review**	• **Contracting for reliability**
• **Load/strength interactions**	• **Reliability growth models and displays**
• **Software reliability tools**	• **Cost of unreliability**
• **Sudden death and simultaneous testing**	• **Reliability policies and specifications**
• **Failure recording, analysis and corrective action**	• **Reliability audits**
• **Failure mode effect analysis**	• **Management's role in reliability improvements**

The three regimes for equipment failure are: 1) infant mortality, 2) chance failures, and 3) wear out failures, which are connected to failure rates. Human errors are usually chance failures.

Infant mortality and old age wear out failures are superimposed on chance failures to obtain the typical bathtub failure curve where we typically think of chance failures having a lower failure rate than either wear out failures or infant mortality failures. The idealized bathtub curve is seldom observed for equipment—we have fewer pieces of equipment than we have human failures (deaths) and all human deaths in civilized societies must be reported to government agencies (mandatory reporting for equipment failures is not required).

The death of most equipment must be analyzed with Weibull analysis small samples using (Abernethy 2000) for each failure mode, and software makes the analysis task easy (Fulton 2004). In many cases a simple arithmetic technique of MTBF or MTTF is frequently used as a reliability precursor mixtures of failure modes that occur.

Most reliability tools are practical engineering tools seldom studied in depth at most universities. Usually the tools must be learned as supplements of continuing education either by home study or by short courses—see the reading list (Barringer 2004 a).

A simple precursor of reliability is a criterion called mean time to failure for non-repairable items and mean time between failures for repairable items. Consider the seal MTTF details in Figure 1 showing the effects of a change in failure criteria caused by new regulations.

This MTTF data from production, maintenance, and purchasing records

Remember: MTTF is a yardstick—not a micrometer!!

Chemical Plant ANSI Pump Life

Figure 1: MTTF Before And After Regulatory Changes

The MTTF decline in Figure 1 results from a more severe criteria for failure. MTTF/MTBF indicators help forecast the number of pump repairs expected during a time interval and thus help plan maintenance demands on resources and costs.

Some systems are simple series models without redundancy as shown in Figure 2 where failure of a single device causes the entire system to fail.
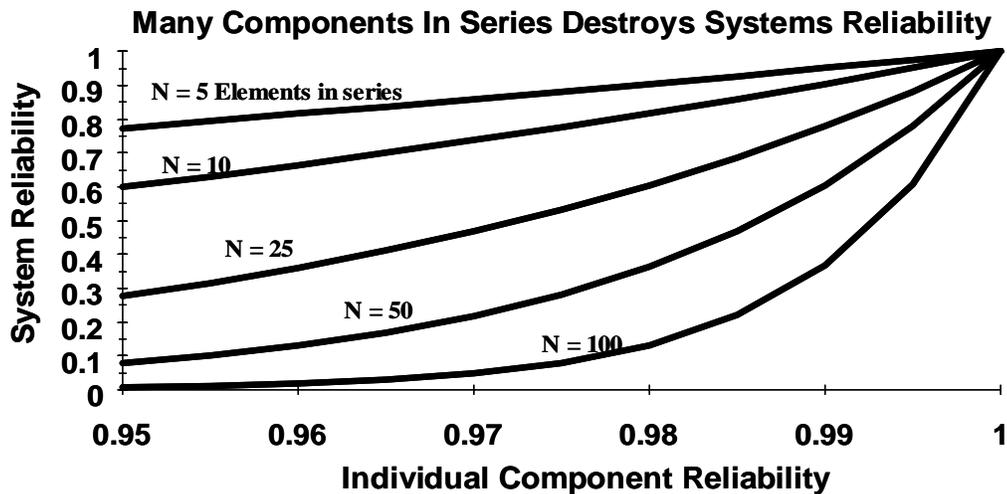

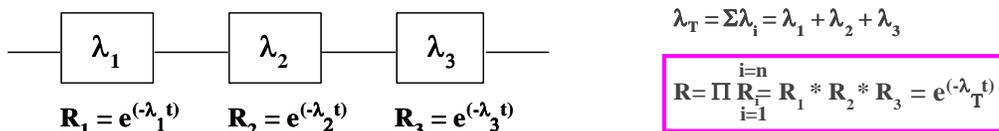

$$\lambda_T = \Sigma \lambda_i = \lambda_1 + \lambda_2 + \lambda_3$$

$$R = \prod_{i=1}^{i=n} R_i = R_1 * R_2 * R_3 = e^{(-\lambda_T t)}$$

$$R_1 = e^{(-\lambda_1 t)} \quad R_2 = e^{(-\lambda_2 t)} \quad R_3 = e^{(-\lambda_3 t)}$$

Individual Component Reliability

Figure 3: Simple Parallel System Reliability

Financial failure risk is reduce for dual or triple (or more) redundancy at the expense of more investment. Financial outcomes and can be calculated with standard NPV calculation sheets as the sustaining "cost" is know for each year and acquisition cost for each scenario can be estimated.

For those needing modeling/calculation assistance, the no-cost RAPTOR block diagram software developed by the US Air Force is available for building complex reliability models (Barringer 2004b). Data is required to drive all reliability models and a limited Weibull database is available (Barringer 2004c), and data for reliability models should come from your own failure database which reflects: 1) grade of equipment purchased, 2) maintenance/operating strategies employed, and 3) organization of the database to clean the data using good practices such as inclusion of suspended (censored) data, and identification of the data taxonomy (CCPS 1998).

An area of poor reliability lies in problems associated with humans for rapid response when monitoring, controlling, and maintaining systems. The roots of failures, when broken into a Pareto distribution, are: 38% for humans, 34% for procedures/processes, and 28% for equipment. Human error probabilities = (number of errors)/(number of opportunities for error) and human error rates = (number of errors)/(total task duration). Table 2 shows the human probability of failure in a control room to correctly diagnose an abnormal event—reliabilities are obtained by taking the complement of probabilities of failure (AIChE 2000). This infers that automation of control room functions is very important for improving system reliability. The popular, but erroneous,

Table 2 Time Available For Diagnosis Of An Abnormal Event After Control Room Annuciation	
Time (minutes)	**Probability Of Failure (%)**
1	~100
10	50
20	10
30	1
60	0.1
1500	0.01

concept is humans are reliable and equipment is unreliable which leads to overemphasizing hardware faults and underemphasizes human faults. Human unreliability is often the dominate factor in unreliability issues.

To an engineer, most issues concerning reliability are related to things (not people)—things that happen and things that mitigate failures. To managers, most issues concerning reliability are related to costs—particularly the costs for loss of the process. This requires converting things into money, which drives the need for alternatives. Seldom is the "best" engineering idea implemented because in the real world money is scarce and the first cost is rarely the last cost as things need constant attention and maintenance which ties all issues to life cycle costs and net present value calculations for the time value of money.

Life Cycle Costs

Life cycle costs (LCC) refer to all costs associated with acquisition and sustaining costs for ownership of a product or system over its full life (Fabrycky 1991), (SAE 1999). The usual figure of merit is net present value (NPV).

NPV is a financial tool for evaluating economic value added. It is the present value of an investment's future net cash flows, minus the initial investment for a given discount rate hurdle. The present values for each year of the project are summed for the net present value. Net cash flows are a measure of a company's financial health. Discount rates are the interest rates used in discounting future cash flows. The discount rates include the cost of money, bank and company administration costs, and risk costs for the lender—they are always larger than Federal Bank rates. For an entire project, the life cycle cost number requires a positive NPV. Bigger positive NPVs are better.

Project elements cannot easily show profits/savings for each equipment component, and decisions are made in selecting equipment based on the **least negative** NPV, where smaller negative NPV is better criteria. Many improvement projects will have positive NPV along with internal rates of return (IRR) as a second criteria insisting on higher rates of returns on many small projects that must jump a very high hurdle to hold down the expenditure for capital money—particularly if the company lacks access to financial money for improvements.

All LCC task**s** require comparisons of alternative**s**—note the word alternatives is plural. In every LCC task, conflicting issues are obvious:

- Project engineers want to minimize capital expenditures
- Accounting wants to maximize NPV
- Shareholders want to maximize dividends/share price
- Production wants to maximize uptime hours
- Maintenance engineers want to minimize repair hours
- Reliability engineers want to avoid failures

All parties want someone else to put the numbers together to justify their love affair with the project or equipment, which justifies their decisions.

Business is about time, money, and alternatives. Time and money are both in short supply. A single alternative is without choice and unwise because the default position is to do nothing. The LCC concept merges time and money together to arrive at a single indicator called NPV for each alternative. NPV numbers prioritize the projects to select the winner from the alternatives so you buy right rather than only buying cheap.

Techniques used for finding LCC are available in training formats (Barringer 2004d). Technical papers are available for download from the Internet as PDF files (Barringer2004e).

Making the life cycle cost calculations is easy when you have the data. The difficult effort is how to resolve the chicken or egg dilemma for finding failure data, maintenance data, and other details involved in the sustaining cost as the acquisition cost is usually the only accurate number you have as it is a quotation. You need reliability engineering details to find when things die.

Failure data and repair time data can be converted into statistical format using WinSMITH Weibull software for use in reliability calculations. (Fulton 2004)

Few individuals claim knowledge of sustaining cost facts until someone else puts numbers on the table—then the critics are numerous for "correcting" the proposed numbers. Follow the scientific method: build a hypothesis for failures and their cost and then test the hypothesis. When in doubt about the failure data or cost, make an estimate and test the estimate for validity.

Much data needed for LCC comes from operating costs (including electricity, etc.) and maintenance records which show times between failure and repair times. These details are often associated with the field of reliability and maintainability with a direct relationship for finding lower life cycle costs. The cost details should also include costs for lost gross margin for outages of systems when it is appropriate. Some of the failure data is from simple arithmetic calculations and other data follows the preferred method from Weibull databases.

Conditions for installation, operation, and maintenance influence both failures and failure costs, which are susceptible to equipment grades for changing the financial performance. Often Monte Carlo computer simulations, using random numbers, are required to find cost variability for different equipment grades.

Your can build simple, low cost Monte Carlo reliability models using software available from the Internet which is useful for driving life cycle cost decisions. (Barringer 2004e) The reason for building reliability models is to find where failure cost is occurring and to search for the lowest long-term cost of ownership where system details, when priced-out, provide a clear leading alternative for solving the problems. The reliability models show what's affordable and the less desirable alternatives.

Reliability models, using actual failure data and repair times, give system availability, reliability, maintainability, and other operating system details which allow construction of costs and tradeoffs. A clear definition of failure is important for reliability decisions and the data acquired.

If you do not have data collection systems for your failures, you will seldom make substantial improvements in the reliability of your systems.

Reliability models provide evidence for tradeoff boxes. Engineers need graphics for understanding what's happening to their systems. The tradeoff box has life cycle cost on the vertical axis and effectiveness on the horizontal axis. Effectiveness is the product of availability, reliability, maintainability, and capability of the system to perform. Complex items become simple when you see the results shown in Figure 4. The left hand of Figure 4 symbolizes too many failures and the right hand of Figure 4 symbolizes too much equipment. The sweet spot lies between the extremes.

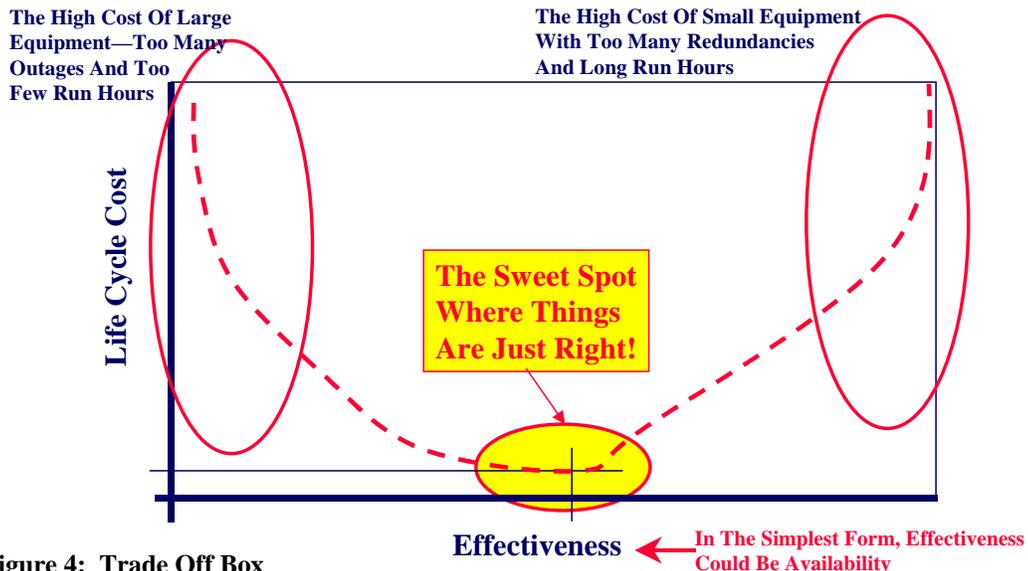

Figure 4: Trade Off Box

What most companies need is the money and control of risk—they rarely need perfect solutions! Life cycle cost helps provide the answers when driven by the tools of reliability engineering. When you have concepts and features on a product or process that generate value, the value must be quantified for inclusion in the life cycle cost model. .

Summary

A reliability policy focuses the organization toward a failure free environment to meet management objectives for the business. Reliability engineering tools predict failures and risks associated with certain actions. Details from the reliability analysis go into life cycle costs models for merging engineering details into a format considering the time value of money. Life cycle concepts rely heavily on reliability and maintainability technology issues to convert ideas into hard, engineering facts which convert issues into a monetary values for making trade-off decisions about $Risks.

The first cost for procurement is not the last cost. Procurement cost may represent only a small fraction of the total cost during the life of an item, and in other cases, it may be a large portion of the total life cycle costs—general rules of thumb have much variance.

The engineering facts must be converted into financial details of NPV and IRR with a selection of the best alternative from several courses of action. The decisions you make up front will be with you for many years so it's important to justify risks and improvements using the best tools available.

Without reliability details about failures, NPV are difficult to calculate for making correct business decisions about tradeoffs with failure avoidance for reliability as a business focus.

If your owners, customers, or the general public are unhappy about reliability of your systems, improvements must be made—that is a call for change. To get change, you must make a change. If improvements are not voluntary and community outrage is high, trailing legislation will surely follow in ways seldom to your advantage. Unreliability must be quantified and resolved quickly for business purposes. Occasionally reliability begins at low levels in the organization with long incubation times before recognizable progress is recorded; however in private enterprise, high system reliability is best-achieved top down with policy statements to quickly put the organization to work for reaching a target in reasonable time frames.

Biography

Paul Barringer, P.E. is a manufacturing, engineering, and reliability consultant with more than forty years of engineering and manufacturing experience in design, production, quality, maintenance, and reliability of technical products. Experienced in both the technical and bottom-line aspects of operating a business with management experience in manufacturing and engineering for an ISO 9001 facility. Industrial experience includes the oil and gas services business for high pressure and deep holes, super alloy manufacturing, and isotope separation using ultra high speed rotating devices.

He is author of training courses: **Reliability Engineering Principles** for calculating the life of equipment and predicting the failure free interval**, Process Reliability** for finding the reliability of processes and quantifying production losses, and **Life Cycle Cost** for finding the most cost effective alternative from many equipment scenarios using reliability concepts.

Barringer is a Registered Professional Engineer, Texas. Inventor named in six U.S.A. Patents and numerous foreign patents. He is a contributor to **The New Weibull Handbook**, a reliability handbook, published by Dr. Robert B. Abernethy.

His education includes a MS and BS in Mechanical Engineering from North Carolina State University. He participated in Harvard University's three-week Manufacturing Strategy conference.

Other reliability and life cycle costs details are available at **http://www.barringer1.com**
